Requirement Analysis

Business Requirements

Requirement Analysis:

The first stage of requirement analysis is to identify the business requirements of the Auto Ticket Classification system. The system is designed to reduce the manual effort required by IT staff when classifying Incident tickets.

The main requirement is that the system should automatically classify IT incidents based on the information provided in the incident description. The system should be able to identify the type of issue and assign the appropriate Category without requiring manual intervention.

The system should also assign the appropriate Subcategory based on the selected Category. This helps maintain a structured and standardized classification of incidents.

Another important requirement is automated communication. After an Incident is created and processed, the system should be able to send an automated email notification to the caller.

The ticket information should be stored in a structured and standardized format so that it can be easily understood and managed by IT staff. The solution should also be simple to maintain and should allow additional keywords and classifications to be added in the future.

Main Business Requirements:

- Automatic Classification
- Automatic Category and Subcategory Assignment
- Automated Email Notification
- Standardized Ticket Information
- Easy Maintenance and Future Extension

Functional Requirements

Functional Requirement Analysis:

The functional requirements describe how the Auto Ticket Classification system should work. The main input to the system is a newly created Incident. The Incident contains information such as the Short Description and Description, which provide details about the user's problem.

When a new Incident is created, the Flow Designer flow should automatically start. The flow checks the information available in the Incident and searches for predefined keywords related to different IT issues.

Based on the identified keyword, the flow should update the appropriate Category and Subcategory fields. This removes the need for IT staff to manually select these fields for every ticket.

For example,

Short Description: “My Wi-Fi is not working.”

Keyword: Wi-Fi

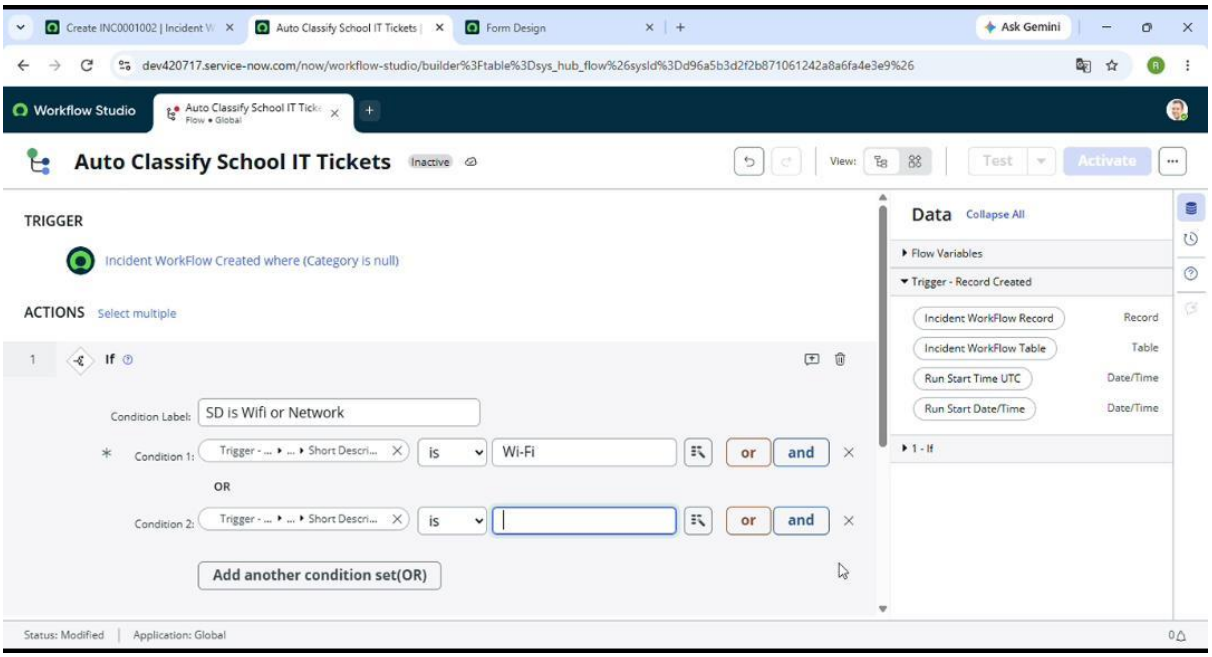

Issue Type: Network-related problem

Category: Network

Subcategory: Wi-Fi

The system can also perform an automated email notification action after the ticket is processed. This provides information to the caller without requiring IT staff to manually send an email.

The functional process can therefore be represented as Incident **Input → Keyword Checking → Classification → Category and Subcategory Update → Email Notification.**

Flow Planning and Testing Requirements

Implementation and Test Requirement:

The implementation of the Auto Ticket Classification system begins by creating a Local Update Set named Project Update Set and making it the current Update Set. After this, a new flow is created in ServiceNow Flow Designer with the name Auto Ticket Classification.

The flow is configured to start when a new Incident record is created. After the trigger, the flow checks the Short Description and Description for predefined keywords. When a matching keyword is identified, the flow updates the Category and Subcategory fields according to the classification rule.

The basic flow structure is **Incident Created → Check Short Description/Description → Check Keyword → Update Category/Subcategory → Send Email.**

Testing is required to confirm that the flow works correctly.

Example:

Short Description :"Wi-Fi is not working."

Keyword: Wi-Fi

Category: Network

Subcategory: Wi-Fi

The test should also verify that the caller receives the automated email notification after the Incident is processed. Successful testing confirms that the main functional requirements of the Auto Ticket Classification system are working as expected.
